Evolving schema representations in orbitofrontal ensembles during learning

Jingfeng Zhou[1][✉], Chunying Jia[2], Marlian Montesinos-Cartagena[1], Matthew P. H. Gardner[1], Wenhui Zong[1] & Geoffrey Schoenbaum[1][✉]

How do we learn about what to learn about? Specifically, how do the neural elements in our brain generalize what has been learned in one situation to recognize the common structure of—and speed learning in—other, similar situations? We know this happens because we become better at solving new problems—learning and deploying schemas[1–5]—through experience. However, we have little insight into this process. Here we show that using prior knowledge to facilitate learning is accompanied by the evolution of a neural schema in the orbitofrontal cortex. Single units were recorded from rats deploying a schema to learn a succession of odour-sequence problems. With learning, orbitofrontal cortex ensembles converged onto a low-dimensional neural code across both problems and subjects; this neural code represented the common structure of the problems and its evolution accelerated across their learning. These results demonstrate the formation and use of a schema in a prefrontal brain region to support a complex cognitive operation. Our results not only reveal a role for the orbitofrontal cortex in learning but also have implications for using ensemble analyses to tap into complex cognitive functions.

Rats were trained on an odour-sequence task[6,7]. On each trial, they sampled one of 16 odours and decided whether to respond to obtain reward (Fig. 1a). The odours were organized into two sequence pairs (Fig. 1b; S1a–S1b and S2a–S2b), each with six trials (positions; P1–P6). All but two odours had a fixed association with reward, so for most of the 24 trial types, information about sequence was not required, although it could be used to anticipate reward. However, for the odours at P4 and P5 in S2 (S2a4+, S2b4−, S2a5− and S2b5+), the meaning of the same odour differed between the two subsequences (S2a and S2b). At these positions, the rats had to maintain the sequence information across several trials to perform correctly.

After shaping, the rats were trained on five new problems in which the sequence and reward structure (Fig. 1b) remained the same, but 16 new odours were used (problem 1–problem 5; Fig. 1c). Thus, for each problem, the rats had to learn how the new odours fit into the sequence template (that is, the schema) learned in previous problems. Rats were trained for 15–23 days on each problem. To align the analyses, each dataset was truncated to 15 sessions, including the first 14 sessions of learning and data from the session with the best performance thereafter (Extended Data Fig. 1). Behaviours reflecting the sequences emerged during this training, including correct responding on trial types that required recall of the sequences (Fig. 1d–g, Extended Data Fig. 2) as well as changes in the time the rats spent to initiate each trial—their poke latency—reflecting reward availability on the current and upcoming trials (Fig. 1h–j).

Reduced neural dimensionality
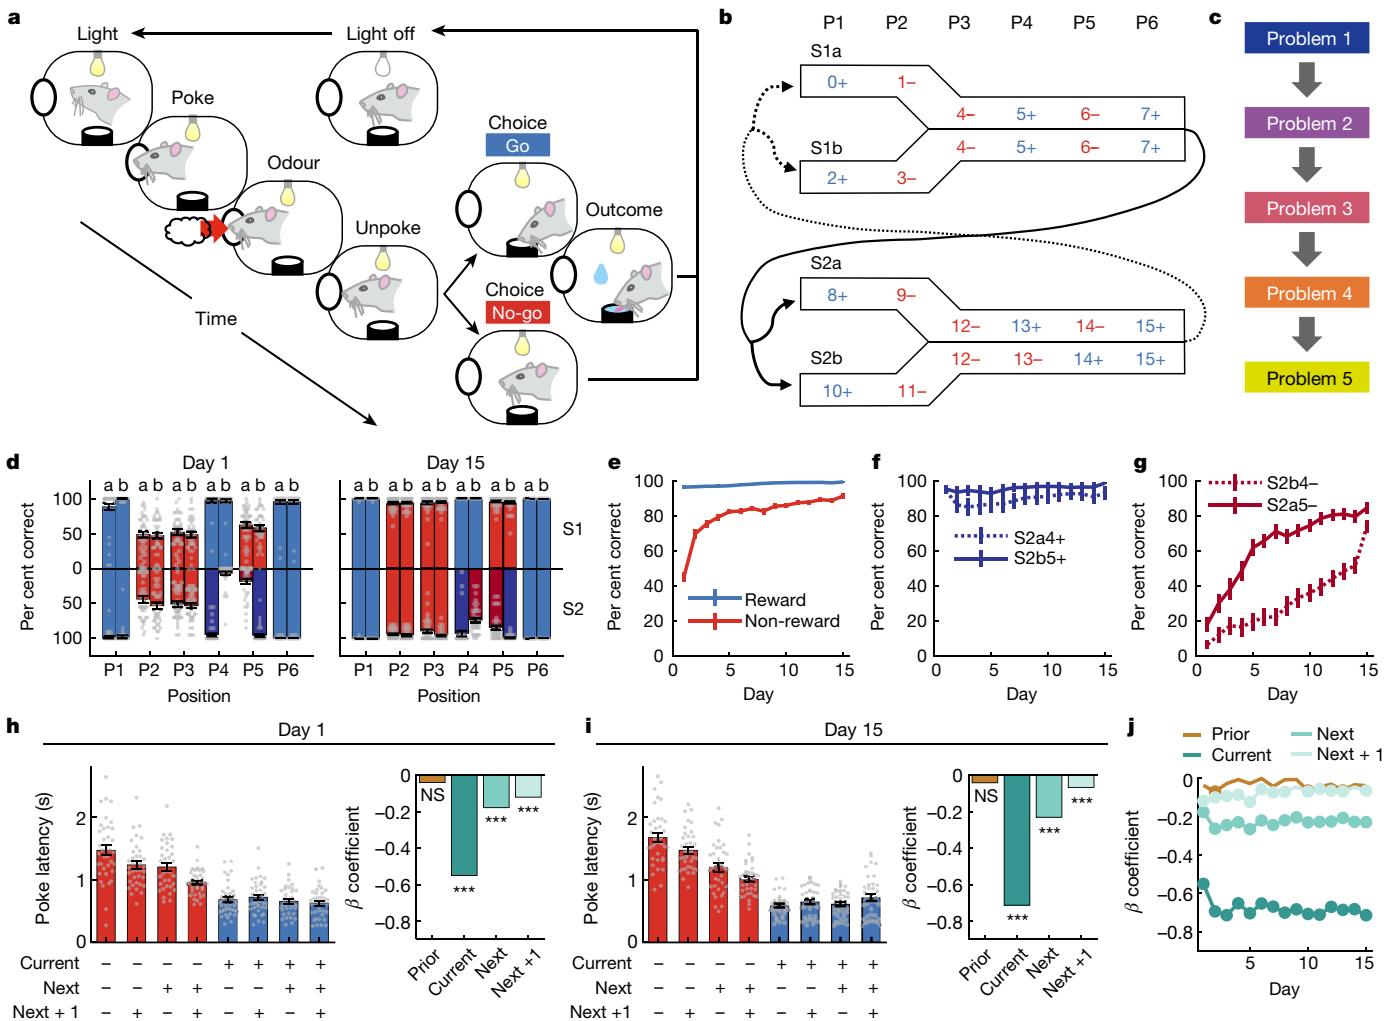

The numbers of neurons ($n = 1,122.9 \pm 41$, mean ± s.d.; all problems and rats combined; Extended Data Fig. 3a, b, Supplementary Tables 1, 2)

recorded in the orbitofrontal cortex (OFC) and their overall activity (Extended Data Fig. 3c, d) remained stable across days. The percentage of neurons that were selective among the 24 trial types decreased during learning, whereas the percentage of neurons that were sensitive to reward increased (Extended Data Fig. 3e, f). We used an independent component analysis (ICA) followed by a linear discriminant analysis (LDA) to reduce the dimensions in the single-unit data (480 trials × N; N = approximately 1,123 neurons per day × 4 epochs × 8 time points; the 4 epochs are: 'light', 'poke', 'odour' and 'unpoke'; peri-event time at each epoch was: −0.2 to 0.6 s; bin size = 0.1 s; Fig. 2) and then measured the Mahalanobis distance (that is, representational dissimilarity) between each pair of trial types within the resultant activity space (that is, linear discriminant components (LCs)). This revealed a marked compression of the activity space from day 1 to 15 (Fig. 2a, b, Extended Data Fig. 4a–h). The distribution of variance on the LCs shifted across days of training from a high-dimensional pattern to one associated with lower dimensionality (Fig. 2c, d, Extended Data Fig. 4i, j). As a result, during learning, the percent of variance explained by the first three LCs increased (Fig. 2e) and the number of LCs that explained 80% variance decreased (Fig. 2f), especially for the S1 sequence, where maintaining sequence information was not required for correct responses (Fig. 2g). These changes are consistent with the formation of a neural schema.

Evolving cross-problem and cross-subject decoding

The observed neural representation on each problem is a projection of the true neural representation onto a neural activity space defined by the currently recorded neurons, which can be studied within a lower-dimensional subspace or neural manifold[8]. If the activity in

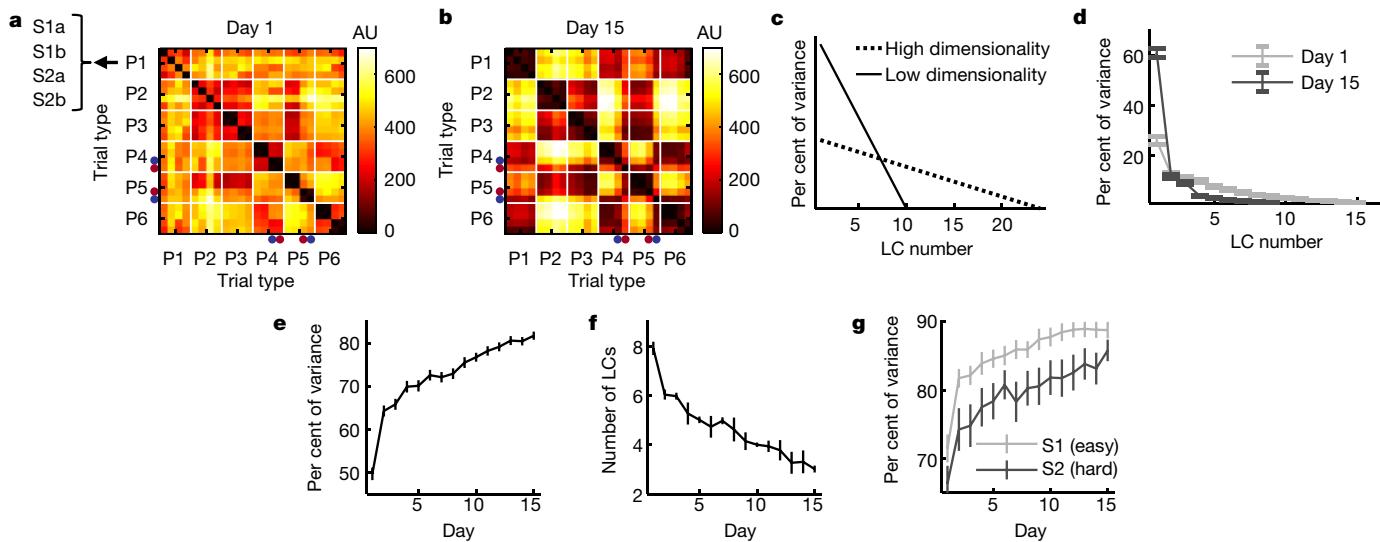

Fig. 1 | Task design and behaviour. a, Single-trial illustration of the odour-sequence task. **b**, Sixteen odours were organized into two pairs of sequences (S1a–S1b and S2a–S2b), each consisting of six trials or positions (P1–P6). Blue +, rewarded; red −, non-rewarded; 0–15, odour identities; arrows indicate transitions between sequences. **c**, Each problem uses the same odour-sequence structure but with 16 new odours. Nine rats were trained successively on five problems after shaping. Behavioural analyses combined the five problems and nine rats with data aligned to training days. **d**, Per cent correct in S1 (above *y*-axis) and S2 (below *y*-axis). Blue, rewarded; red, non-rewarded. Darker colours indicate trial types that require rats to use past sequences. **e**–**g**, Per cent correct during learning averaged for trials at all positions (**e**) and also shown for trials in S2 at P4 and P5 (**f**, rewarded; **g**, non-rewarded). **h**, **i**, Poke latency (house lights onset to odour port entry) sorted by future rewards on day 1 (**h**, left) and day 15 (**i**, left). A linear regression for the poke latency was fit with four regressors (reward on the prior, current, next and next + 1 trials) for day 1 (**h**; right) and day 15 (**i**; right). NS, not significant; ***$P < 0.001$. **j**, Regression coefficients during learning. Round markers indicate statistical significance. *$P < 0.05$; corrected with the Benjamini–Hochberg procedure. **d**, **h**, **i**, $n = 37$ and 36 sessions for day 1 and day 15, respectively. **d**–**i**, Data are mean ± s.e.m. Statistics are presented in Supplementary Table 3.

the OFC is converging onto a schema with learning across problems, the true neural representation should become increasingly similar with learning across each problem. However, changes in the recorded neurons across days and problems can cause the observed neural representations to appear misaligned, even if they reflect the same true neural representation. To overcome this problem, we used a canonical correlation analysis (CCA) to align the dimensionality-reduced neural datasets acquired each day on different problems[8]. The CCA finds linear transformations for pairs of neural datasets, such that the transformed datasets are maximally correlated. This results in canonical components (CCs) describing the neural activities from each dataset within a common neural manifold. A higher correlation between a given pair of CCs means better alignment of the two datasets on this particular dimension, consistent with a more generalized, as opposed to idiosyncratic, neural representation (Extended Data Fig. 5a).

If a neural schema exists, this procedure should reveal alignment of the neural activity across problems; stronger schema should result in stronger alignment across problems. Furthermore, we should be able to use the CCs derived from this analysis to identify or map the trial types from the CCs derived from the analysis of other problems. To test these predictions, we conducted a decoding analysis in which we used 60 CCs generated from two of the five problems as training sets, and 60 CCs generated from two of the remaining problems as test sets (Extended Data Fig. 5b). Comparing the corresponding CCs, we found strong correlations between the CCs derived from the training and test data, with a notable increase from day 1 to day 15, consistent with the development of a generalized neural code—the neural signature of a schema—across problems (Fig. 3a, Extended Data Fig. 6).

A closer examination of the activity of the paired CCs revealed that the first three exhibited a clear relationship to specific task features: 'current value' defined by whether the trial was rewarded, 'odour overlap'

Fig. 2 | Dimensionality of the task representation. The neural data combined five odour problems and nine rats with alignment to the training days. For each repeat, the trial order within each one of the 24 trial types was shuffled for each neuron to create a new pseudo-ensemble. An ICA was performed on the neural firing data to extract a low-dimensional representation of the neural data (480 trials × 100 neural dimensions), which then underwent an LDA with the labels of 24 trial types. **a**, **b**, Dissimilarity matrices on day 1 (**a**) and day 15 (**b**) showing the Mahalanobis distance between each pair of trial types in the LDA activity space (averaged across 500 repeats). Within each position: S1a, S1b, S2a and S2b. Blue dots, S2a4+ and S2b5+; red dots, S2b4− and S2a5−; AU, arbitrary units. **c**, Theoretical variance distributions. **d**, Actual variance distributions on day 1 and day 15. **e**, The per cent of variance explained by the first 3 LCs. **f**, The number of LCs needed to explain 80% variance of the data. **g**, The per cent of variance explained by the first three LCs for sequences S1 and S2 separately. **d**–**g**, $n = 500$ repeats; data are mean ± s.d. Statistics are presented in Supplementary Table 4.

defined by whether the odour was unique or shared, and 'positional alternation' defined by an alternating pattern along each sequence. The relationships between the first three CCs and their respective task features increased in strength from day 1 to day 15 (Fig. 3a–c), generally improving cross-problem decoding of the trial types (Fig. 3d, e, aligned). Notably, the accuracy of this cross-problem decoding was disrupted when the order of the 24 trial types was shuffled independently in each problem to misalign the sequence structure (Fig. 3d, e, misaligned); this demonstrates the dependence of the decoding on the generalizable structure of the problems—direct evidence for the construction of a neural representation of the odour-sequence task capable of generalizing across problems. This process of construction was also evident in the marked changes in the cross-problem decoding that occurred with learning (Fig. 3d, aligned), particularly after the first few days of training (Fig. 3f), which reflected bidirectional changes in the ability of the decoder to correctly distinguish sequences (Extended Data Fig. 7a, b) and positions (Extended Data Fig. 7c–f). Specifically, cross-problem decoding of the positions improved during learning, whereas cross-problem decoding within each position tended to diminish for odour-unique positions (behaviourally-similar but discriminable by odours; P1–P2), while improving at odour-overlapping positions (behaviourally-distinct but discriminable only based upon previously presented odours; P4–P6, S2).

While the changes in cross-problem decoding presumably reflect convergence of the neural representations across problems within each subject, it is not clear from this analysis whether neural representations in the OFC also converged on a common solution or schema across subjects. Although it is not necessary, the ability to decode across subjects would require the presence of a common neural representation or schema. To address whether this ability is present, the rats were divided into two groups; rats in one group were used to generate CCs for training sets, whereas rats in the other group were used to generate CCs for test sets (Extended Data Fig. 5b). Again, we found strong correlations between CCs from the training and test data (Fig. 4a, Extended Data Fig. 8), the first three CCs developed increasingly strong relationships to the same three task features (current value, odour overlap and positional alternation) during training (Fig. 4a–c), and again these and the other CCs allowed successful decoding of the different trial types (Fig. 4d, e), which evolved with training (Fig. 4f, Extended Data Fig. 9).
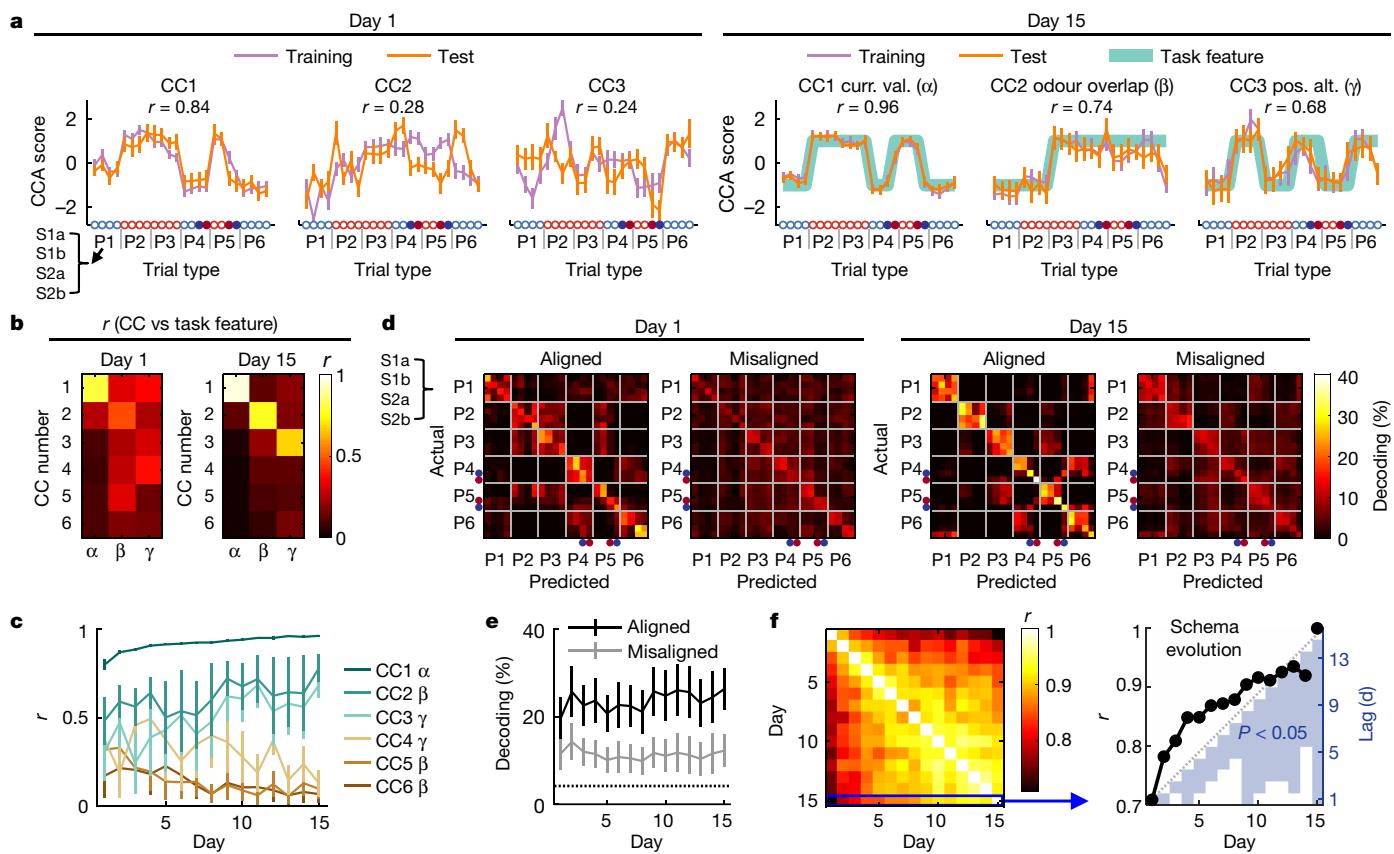

Accelerating learning and neural changes

Poke latency measures how quickly the rats initiate a trial after the house lights come on; rats responded more quickly when they expected more reward in the future than when they expected less reward (Fig. 1h–j). This pattern developed with learning on each problem, and the speed at which the pattern emerged during learning became faster across problems (Fig. 5a, b, Extended Data Fig. 10). This accelerated learning is evidence of the operation of a schema reflecting knowledge of the sequences. While the temporal resolution of our neural data analysis demonstrating schema formation is by necessity different from resolution of the behavioural analysis demonstrating schema operation, the two should be related if the schema is manifest in the neural activity in OFC. Consistent with this idea, we found that both dimensionality reduction (Fig. 5c) and schema evolution (Fig. 5d) accelerated similarly.

The importance of identifying schemas

Learning what to learn about and generalizing from one situation to another is arguably one of the most fundamental abilities that distinguishes higher intelligence. The effects of the resultant schemas can be seen in simple motor or sensory processing, in which learning one skill facilitates acquisition of another—knowing how to ski helps us learn to snowboard—but they are also evident in experience-based improvements in more abstract problem-solving skills. From buying groceries to planning experiments, we get better at navigating new situations if we have experienced similar ones in the past.

Here we have identified a neural signature of schema formation in rats using sequences of odours to effectively retrieve rewards. As they were given new sets of odours, the rats were quicker to exhibit behaviour reflecting a knowledge of the sequences. Against this backdrop, we found that neural activity in OFC converged on a common

Fig. 3 | Cross-problem decoding. The training (480 trials × 60 CCs) and test (480 trials × 60 CCs) datasets were separately obtained through dimensionality reduction and then manifold alignment on pseudo-ensembles from pairs of odour problems. **a**, The first three CCs in training and test from a single repeat. *r*, correlation coefficient of paired CCs from training and test sets; *n* = 480 trials for each CC; Pearson correlation. representation of the task. This convergence was evident in a reduction in the number of neural dimensions required to represent the task and in improved alignment of neural activities across both problems and subjects, neural changes that accelerated with accelerated learning. Although these neural changes were correlative and thus likely to track increases in efficiency of motor behaviours and other covariates[9], the rats were pre-trained on the basic skills required in the task, and the improved alignment in neural activity reflected improved representation of critical task-relevant cognitive concepts, some of which were idiosyncratic features of the odour-sequence problems. This work joins a small but growing number of studies that have found neural correlates of schemas in other brain regions[10–16], including generalization of single-unit and ensemble firing patterns to incorporate new exemplars of a class[11].

The identification of a neural signature of schema formation in the OFC is intriguing in light of this area's involvement in flexible problem solving, learning set formation and even generalization[17–19]. A common thread across these settings is the need to use the causal structure of the relationships defining the task at hand to support normal behaviour[20]. This observation has led to the hypothesis that the OFC is part of a circuit required for cognitive mapping, which includes other prefrontal areas and hippocampus[6,20–24]. The current correlative data

suggest that the OFC may have a specialized role in this circuit, allowing the meta-structure or rules that characterize individual maps to be abstracted and deployed to aid the formation of new maps. This more specialized function would be consistent with well-appreciated data showing that the OFC is necessary when behaviour requires a cognitive map and with less well-appreciated evidence that this is only true when new information—a new map—is necessary[25]. This is evident in devaluation[26], sensory preconditioning[18] and over-expectation[27] tasks, during which the OFC is required in phases where an established map must be adjusted to reflect new information. By contrast, when behaviour does not require the integration of new information, in these as well as other settings[28–30], the OFC tends to be not necessary.

More broadly, this study identifies a neural signature of schema formation in a prefrontal brain region and for information that is not easily characterized as simply reflecting optimization of motor or sensory processing. The pattern of neural activity in the OFC, identified using dimensionality reduction and manifold alignment, converged onto a common solution for a complex cognitive operation. Further, the resultant cognitive schema was neurally generalizable not only across problems within the same brain, but also across brains[14]. That the OFC networks in different subjects converged on a common neural representation is key, since it implies that individuals organize information in a

Fig. 4 | Cross-subject decoding. As in Fig. 3, except that training and test sets were separately obtained from pairs of rat groups rather than pairs of problems. similar format, even for advanced prefrontal functions. This is important for neuroscience, since it suggests that we can identify even these types of functions at a granular level by studying groups of subjects. It also has implications for using brain–machine interfaces to enhance functions beyond sensory perception or simple motor activity, since if neural schemas for complex cognitive operations are not specific to individuals, they may be defined from a general understanding or knowledge of their shape, rather than needing to be tailored to each individual for each problem, which would be much less practical.

Article

Methods

Rats

Subjects were nine male Long-Evans rats (Charles River, 175–200 g, ~3 months old) housed individually on a 12 h light:dark cycle and given ad libitum access to food in an animal facility at the AAALAC-accredited animal care facility at the National Institute on Drug Abuse Intramural Research Program (NIDA-IRP). Water was removed the day before any testing day, and they received free access to water for 10 min in their home cages each afternoon after testing. If there was no testing the next day, the rats were given free access to water. All behavioural testing was carried out at the NIDA-IRP. Animal care and experimental procedures complied with the US National Institutes of Health (NIH) guidelines and were approved by the Animal Care and Use Committee (ACUC) at the NIDA-IRP.

Odour sequence task

The training was conducted in aluminium boxes (~18 inches on a side) equipped with a port for odour delivery and a well for delivery of sucrose solution. Task events were controlled by a custom-written C++ program and a system of relays and solenoid valves; entries into the odour port and the fluid well were detected by infrared beam sensors. The availability of each trial was signalled by the illumination of two house lights located on the wall above the odour port. Nosepoke into the odour port within 5 s after light onset initiated the trial, leading to odour delivery after a 500-ms delay. Rats were required to remain in the port for an additional 500 ms; the trial was aborted, and the lights extinguished if the rat left the odour port before this time had elapsed. After 500 ms, the rats were free to leave the port, which terminated odour delivery. After port exit, rats had 2 s to respond at the fluid well. On rewarded trials, a response led to the delivery of a sucrose solution (10% w/v; 50 µl) after a random delay ranging from 400 to 1,500 ms. Upon exit from the well, non-responding during the 2-s period, or responding on non-rewarded trials, the house lights were extinguished, indicating the end of the trial and the beginning of the inter-trial interval (ITI). A 4-s ITI followed correct trials, and an 8-s ITI followed trials on which the rat made an error.

On each trial, one of 16 odours was delivered to the odour port. The 16 odours were organized into two pairs of sequences (S1a, S1b, S2a and S2b), described below. The odour identity is indicated by a number, and reward and non-reward are indicated by the positive (+) and negative (−) symbols, respectively: S1a: 0+, 1−, 4−, 5+, 6−, 7+; S1b: 2+, 3−, 4−, 5+, 6−, 7+; S2a: 8+, 9−, 12−, 13+, 14−, 15+; S2b: 10+, 11−, 12−, 13−, 14+, 15+.

Before training with any odours, rats were first shaped to nosepoke at the odour port and then respond at the well for a reward. Then, they were trained to discriminate a single odour pair (one rewarded and one non-rewarded odour) from sequence S1a or S1b. Sessions consisted of a maximum of 480 trials. After rats reached a criterion of >90% correct performance on this initial odour pair, additional odour pairs were added until the rats were able to perform accurately (>75% correct) on every trial type in a session containing all of the odours in sequences S1a and S1b. After meeting this criterion, rats were then trained on odour pair 13/14 from sequence S2, including several reversals. After the third reversal, additional odour pairs were added from sequence S2 if the rats were able to perform accurately (>75% correct) on every trial type in a session containing all the odours in sequences S2a and S2b. Once sequence S2 had been fully introduced in this manner, the rats began sessions containing the full set of sequences (S1a/b and S2a/b). In this final training phase, each sequence was repeated 20 times to make 480 trials in total. Sequences S1a and S1b were always followed by S2a or S2b with roughly equal probability (0.55 and 0.45, respectively). Sequence S2a and S2b were always followed by S1a or S1b also with slightly more dissymmetry in probability (0.67 and 0.37, respectively). The overall sequence was repeated from start to finish in each session: S1b, S2a, S1a, S2a, S1a, S2b, S1b, S2b, S1b, S2b, S1b, S2a, S1b, S2b, S1a, S2a, S1a, S2b, S1a, S2a, S1a, S2b, S1b, S2a, S1b, S2a, S1b, S2b, S1b, S2a, S1b, S2b, S1a, S2a, S1a, S2b, S1a, S2a, S1a, S2b, S1a, S2a, S1b, S2a, S1b, S2a, S1a, S2b, S1a, S2a, S1a, S2a, S1a, S2b, S1b, S2b, S1b, S2b, S1b, S2b, S1b, S2a, S1a, S2a, S1a, S2b, S1b, S2b, S1b, S2b, S1b, S2a, S1b, S2b, S1a, S2a, S1a, S2b, S1a, S2a.

Rats trained on the full set of sequences until they were able to perform accurately (>75% correct) on every trial type in a session, then electrode arrays were implanted bilaterally in the OFC.

Surgical procedures

Rats were implanted with two drivable bundles of 16 electrodes (32 electrodes in total), made from nickel-chromium wires (25 µm in bare diameter; AM Systems), in bilateral OFCs (AP: 3 mm, ML: 3.2 mm). Each wire bundle was housed in a stainless-steel hypodermic tubing (27 gauge, 0.01625 inch OD, 0.01025 inch ID) and cut with a pair of fine bone-cutting spring scissors (16144-13; Fine Science Tools) to extend 1.5–2 mm beyond the end of the tubing inside the brain. The tips of wires were initially placed at 4.2 mm ventral from the brain surface. After surgery, rats were given cephalexin (15 mg kg^{-1}) orally twice a day for two weeks to prevent any infection.

New odour problems

After the pre-training with the first odour set, electrode implantation, two weeks of recovery and one-week of reminder training on the original odour problem, the rats were successively given five new odour problems (1–5) to learn. These problems consisted of 16 new odours, arranged in sequences with the same structure as the original odour problem. Single-unit activity was recorded bilaterally from OFC during learning of each new problem, which took from 15–23 days. The neural dataset was truncated to 15 days on each problem. Data on days 1–14 were from the first 14 days of training on each problem; data on day 15 were taken from the day of the best performance between days 15–23.

Single-unit recording

Electrophysiological signals were recorded with the Plexon Multichannel Acquisition Processor (MAP) systems (v.2.7.0; Plexon). The initial signals collected by the electrodes were sequentially amplified through a headstage (20×), a differential preamplifier (50×), and a final acquisition processor (1–32×). A band-pass filter (250–8, 000 Hz) was used to isolate spike activities, and a threshold was set manually for each active channel to capture unsorted spikes. Timestamps for behavioural events were sent to the Plexon system, synchronized and recorded alongside the neural activity.

Spikes were sorted later offline to remove noise and isolate single units using Offline Sorter (v.4.0; Plexon) with a built-in template-matching algorithm. In short, in a 2D view of spike features (for example, principal component (PC)1, PC2, PC3, spike valley and nonlinear energy), a small group of spike waveforms was manually selected to generate an averaged spike template. In each channel, one or more spike templates were created based on their waveform shapes, visual discriminability, and their signal-to-noise ratios. Other waveforms were then assigned to clusters on the basis of their distances (that is, sum-of-squares difference) to all the templates with an adjustable fit tolerance. The waveform was assigned to one cluster if its minimal distance was less than the fit tolerance for the template. Sorted files were saved as NeuroExplorer (v.4.0; Nex Technologies) formatted files to extract unit and behavioural event timestamps, which were then exported to MATLAB (2019a; MathWorks) for further analysis.

Between odour problems, the electrodes were advanced ~120 µm to change the neural population being sampled. Within a given problem, the electrodes were not advanced. However, we make no claims regarding whether single units recorded on different days within the same problem are the same or different neurons.

Quantification and statistical analyses

The number of rats and the number of neurons were not predetermined by any statistical methods but are comparable to those reported in previous publications from our and other labs[6,8,31–33]. All data were analysed using MATLAB (2019a; MathWorks).

Peri-event spike dynamics

Each trial was divided into six epochs associated with different task events: light, poke, odour, unpoke, choice and outcome. On rewarded trials, the time of well-entry was labelled as choice. Outcome was at the time of reward delivery. On non-rewarded trials, the end of the 2-s window for responding was labelled as choice and a time point 1.5 s after the choice as outcome. Behavioural performance was quantified by the percent of trials on which the rats responded correctly (%correct), their reaction time from the odour port to the fluid well (reaction time), and the latency with which they initiated a trial after light onset (poke latency). The spike train for each isolated single unit was aligned to the onset of each task event for the calculation of a peri-event time histogram (PETH). Pre-event time was set to be 200 ms, and post-event time 600 ms. Spike number was counted with a bin = 100 ms. A Gaussian kernel ($\sigma = 50$ ms) was used to smooth the PETH on each trial. The PETH of each neuron on each task event consisted of 480 trials (rows) and 8 time points (columns).

For neural ensemble analyses, we concatenated PETHs of all neurons across four task epochs (light, poke, odour, unpoke), which resulted in a matrix, $X \in \mathbb{R}^{M \times T}$, Where M is the number of trials (480 trials), and T is the number of concatenated neurons across time (number of neurons × 4 epochs × 8 time points). For each repeat of neural ensemble analyses ($n = 500$ repeats), the trial order within each trial type (24 trial types) for each neuron was shuffled to generate a pseudo-ensemble, which also removes the temporal correlation between neurons within the same trial type.

Dimensionality reduction

To reduce the dimensionality of the neural data, we used ICA (MATLAB toolbox: GroupICATv.4.0b; https://trendscenter.org/software/gift/). ICA is a blind source-separation technique that attempts to decompose an observed multivariate signal into independent source components, which is commonly used as a dimensionality reduction tool to obtain a low-dimensional representation of high-dimensional original data[34–37]. ICA was implemented on a subspace resulted from a principal component analysis (PCA) to reduce the effect of noise.

For the neural data $X \in \mathbb{R}^{M \times T}$, where M is the number of trials ($M = 480$), and T is the number of concatenated neurons, we first ran a PCA on the trial dimension to extract a signal subspace $Y \in \mathbb{R}^{N \times T}$, where N is the number of principal components (PCs) used for further analyses ($N = 100$). The eigenvector matrix is denoted as $V \in \mathbb{R}^{M \times N}$. The noiseless ICA model can be written as $Y = AS$, where $A \in \mathbb{R}^{N \times N}$ denotes the mixing matrix and $S \in \mathbb{R}^{N \times T}$ denotes the latent source matrix. We used the Infomax[38] (https://trendscenter.org/software/gift/), a widely used ICA algorithm, to estimate a demixing matrix $W \in \mathbb{R}^{N \times N}$ such that the components of the estimated source matrix $\hat{S} \in \mathbb{R}^{N \times T}$ are statistically independent. $\hat{S}$ is computed as $\hat{S} = WY$. The estimated mixing matrix $\hat{A} \in \mathbb{R}^{N \times N}$ is the inverse of W: $\hat{A} = W^{-1}$. Back-reconstruction was performed on $\hat{A}$ with the previous PCA transformation to generate $B \in \mathbb{R}^{M \times N}$: $B = V^{+T}\hat{A}$, where $(\cdot)^{+T}$ denotes the transpose of the Moore–Penrose pseudo-inverse of a matrix. Each column of B, representing the weights of the corresponding estimated source $\hat{S}$, is referred to as the trial covariation. The trial covariation matrix B was used as a low-dimensional representation of the high-dimensional neural data.

Owing to the variability in the solution space of the ICA algorithms, we ran the ICA on each dataset 20 times and selected the most consistent run by using an algorithmic consistency metric based on the cross-inter-symbol interference (cross-ISI)[39]. The ISI is a global metric for performance evaluation but only when the ground-truth is known. A smaller ISI between a single run and the ground truth means the estimation is closer to the ground truth. The metric cross-ISI has been developed to overcome the challenge when ground truth is not available for real-world data. In brief, the current run is assumed as the ground truth, the cross-ISI of the current run is computed as an average of all ISIs between the current run and other runs. The run with the lowest cross-ISI (that is, most consistent run) was selected for further analysis.

Representational dissimilarity analysis

An LDA was applied to the low-dimensional representation of the neural data, $B \in \mathbb{R}^{M \times N}$. The LDA finds the components in the underlying subspace that best separate classes. Suppose $x_m \in \mathbb{R}^{1 \times N}$, $m = 1, 2, 3, …, M$, is a vector of the neural data B on trial m ($M = 480$ trials, $N = 100$), c is the number of classes ($c = 24$ trial types), μ is the mean for each class, $\overline{x}$ is the overall mean. The with-class scatter matrix S_w and between-class scatter matrix S_B are defined by:

$$S_W = \sum_c \sum_{i \in c} (x_i - \mu_c)(x_i - \mu_c)^T,$$

$$S_B = \sum_c (\overline{x} - \mu_c)(\overline{x} - \mu_c)^T$$

LDA tries to maximize the ratio of between-class variance and within-class variance of the linearly transformed data:

$$\widehat{W} = \arg \max [(W^T S_B W)/(W^T S_W W)],$$

where W is the argument and $\widehat{W} \in \mathbb{R}^{N \times N}$ is the resulted coefficient matrix for the LDA transformation. The LDA components are computed as $B_{LDA} = B\widehat{W}$, where $B_{LDA} \in \mathbb{R}^{M \times N}$.

The Mahalanobis distance was used to measure the distance or dissimilarity between each pair of trial-type means in the LDA subspace with B_{LDA}. The analysis was repeated 500 times and the averaged dissimilarity matrix was presented as heat map in the main figure. The 24 trial types were plotted in a 2D scatter plot through the classic multidimensional scaling (also known as principal coordinates analysis; MATLAB function: cmdscale) method. For clustering analysis, an agglomerative hierarchical cluster tree was generated with the unweighted average distance method. The clustering results were plotted as dendrograms.

Dimensionality comparison

To estimate task-related neural dimensionality, we examined the distribution of variance on the LDA components[15]. Lower neural dimensionality means fewer neural components should be required to represent a fixed amount of the variance and a fixed number of components should be able to represent a larger amount of the variance. To test for this, we calculated variance explained by each neural component, and asked two questions: (1) How much variance can be explained by the first three neural components? (2) How many neural components are needed to explain 80% variance? To make comparisons of dimensionality reduction between problems, we (1) randomly selected 140 neurons from each odour problem on each day for each repeated analysis; and (2) normalized the variance explained by the first three neural components across days (that is, the explained variance on each day was divided by the peak variance found across days to ensure a 0–1 scale.) and denoted the numbers as the 'dimensional reduction index'. A higher number means lower dimensionality.

Manifold alignment

We used the CCA to align neural activities recorded in different sessions in a lower-dimensional space. CCA uses second-order statistics (that is, cross-covariance) to discover the relationships between two sets of multidimensional variables, by finding two sets of respective linear transformations (that is, canonical coefficients), such that the correlation between two projected variables (that is, canonical variables) is maximized. CCA has been used to align neural activities previously[8,40,41].

Article

Consider $B^{[1]} \in \mathbb{R}^{M \times N}$ and $B^{[2]} \in \mathbb{R}^{M \times N}$ are the low-dimensional representations of the original neural data from two problems after the ICA ($M = 480$ trials; $N = 100$). To avoid overfitting of CCA, we performed PCA on $B^{[1]}$ and $B^{[2]}$ along the neuron dimension, which resulted in $C^{[1]} \in \mathbb{R}^{M \times L}$ and $C^{[2]} \in \mathbb{R}^{M \times L}$, respectively, where L is the number of PCs ($L = 30$) retained. CCA tries to find pairs of canonical coefficient vectors $W^{[1]} \in \mathbb{R}^{L \times L}$ and $W^{[2]} \in \mathbb{R}^{L \times L}$, such that the pairwise correlations between $U^{[1]} = C^{[1]} W^{[1]}$ and $U^{[2]} = C^{[2]} W^{[2]}$ are maximized. Columns in $U^{[1]} \in \mathbb{R}^{M \times L}$ and $U^{[2]} \in \mathbb{R}^{M \times L}$, ordered by paired correlation coefficients, are canonical variables or canonical components (CCs), which were used to represent aligned neural activities between problems.

Classification analyses

We used the LDA for multiclass classification and support vector machine (SVM; MATLAB toolboxes: libsvm-3.22 and ndt.1.0.4)[42,43] for binary classification. In general, classification accuracy was assessed by a leave-one-out cross-validation procedure. Specifically, on each repeat, one trial from each trial type was left out for future testing, and all the other trials were used to create the classifier. For repeats, the trial order for each neuron was shuffled within the same trial type. The trial-order shuffling was repeated 500 times. For each time of trial-order shuffling, the leave-one-out cross-validation was repeated 200 times to estimate the decoding accuracy. The mean decoding accuracy for each trial type as shown in the confusion matrix was the mean across 500 runs (corresponding to 500 times of trial-order shuffling). The statistical significance of the mean decoding accuracy was determined by the 95% confidence interval estimated by running the same decoding process with label-shuffled data.

For each repeat in the cross-problem classification, the five odour problems were randomly assigned with numbers 1 to 5 (these numbers do not indicate the actual problem order). The training set came from one pair of odour problems (numbers 1 and 2), and the test set came from another pair (3 and 4). The neural data from odour problem 5 was randomly combined with odour problem 1 or 2. For the training set, the original neural firing data from the two odour problems (1 and 2) were separately concatenated along the neuron dimension and subjected to dimensionality reduction (ICA + PCA) as described above, which resulted in two matrices $B^{[1]} \in \mathbb{R}^{M \times L}$ and $B^{[2]} \in \mathbb{R}^{M \times L}$ ($M = 480$ trials, $L = 30$ PCs). The manifold alignment was performed on the two matrices to obtain aligned neural activities $U^{[1]} \in \mathbb{R}^{M \times L}$ and $U^{[2]} \in \mathbb{R}^{M \times L}$. $U^{[1]}$ and $U^{[2]}$ are concatenated along the neural dimension as the training data. With the same approach, $U^{[3]} \in \mathbb{R}^{M \times L}$ and $U^{[4]} \in \mathbb{R}^{M \times L}$ are the results of dimensionality reduction and manifold alignment performed on another pair of odour problems, 3 and 4. $U^{[3]}$ and $U^{[4]}$ were concatenated as the test data. If the correlation coefficient between two paired canonical components in the training and tests was negative, the sign of the component in the test set would be flipped. The cross-rat classification followed the same procedure except that the rats, instead of the odour problems, were divided into four groups (1, 2, 3 and 4). Groups 1 and 2 were used to generate the training set, and groups 3 and 4 were used to generate the test set. For cross-rat classification within each problem, 50 neurons were randomly selected from each rat with replacement for each repeat on each day.

For the correlation analyses between the CCA-aligned neural activities and three task features (current value, odour overlap and positional alternation), the dataset was not split into training and test sets. Specifically, for each repeat, the 5 problems (or 9 rats) were randomly divided into two groups (1 and 2). We applied the same dimensional reduction and manifold alignment process described above on the split datasets 1 and 2, which resulted in aligned neural activities: $U^{[1]} \in \mathbb{R}^{M \times L}$ and $U^{[2]} \in \mathbb{R}^{M \times L}$. The Pearson correlations between the first 13 canonical components in $U^{[1]}$ and the three task features were calculated.

Control analysis for cross-problem and cross-subject decoding

The control analysis was intended to mimic a control experiment, in which the components (number of odours, number of trials, likelihood of reward, and so on) remained the same across odour problems but the task structure—the sequence of odours and rewards—differed. In such a control experiment, odours would be presented randomly, with or without reward as in the current experiment, but without any sequence structure. Under these conditions, the trial types within each problem should remain decodable, but cross-problem and cross-subject classifications should fail. To approximate this condition with the current data, we shuffled the order of trial types within each problem before the manifold alignment, which effectively, although not fully, disrupted the sequence structure while leaving other components intact, and then we performed the above analyses to decode the trial types across problems and across subjects.

Reporting summary

Extended Data Fig. 1 | Behavioural performance on each problem and of each rat. a, b, The behavioural learning was assessed by percent of correct (%correct) on rewarded trials ('Go' trials; blue) and non-rewarded trials ('No-Go' trials; red) across training days. Each rat accomplished one session each day. The data was plotted for each problem across rats (**a**; *n* = 9 rats) or each rat across problems (**b**; *n* = 5 odour problems). The days shown on the *x*-axis are the actual training days. Rats showed stable behavioural performance after day 15 and not all rats finished 23 days of training. To align the learning process between problems for further data analyses, we truncated the learning on each odour problem to 15 sessions, consisting of data from the first 14 sessions of learning plus data from the session with the best performance thereafter. Note that the training day of the last sessions with the best performance was referred to as 'day 15', except in this figure. Data are presented as mean ± s.e.m. A two-way ANOVA was performed for each panel (Reward × Day; R × D). See Supplementary Table 8 for detailed statistics.
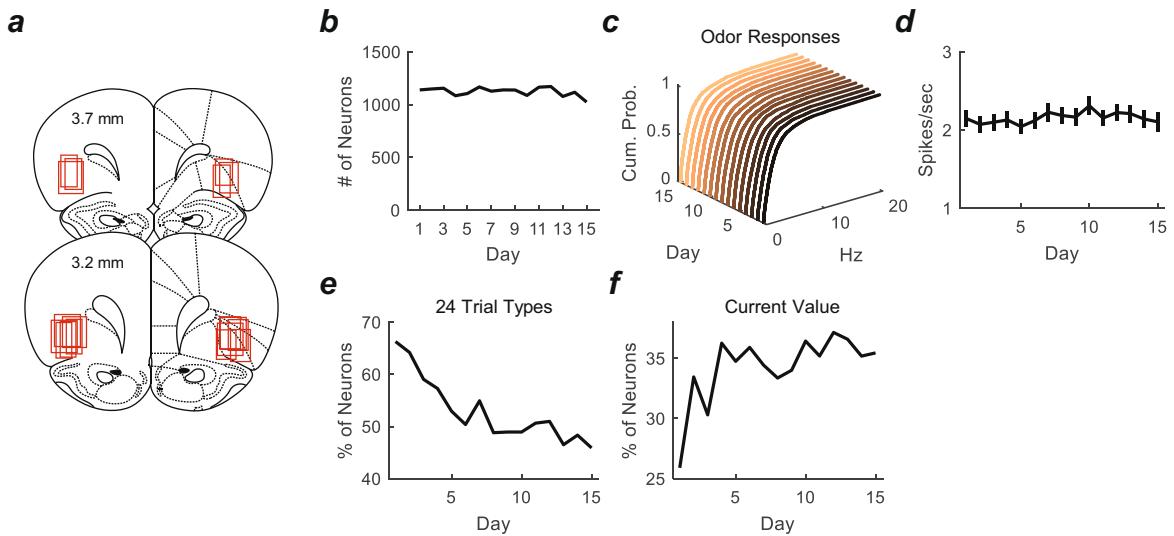

Extended Data Fig. 2 | Reaction time and %correct during learning.
**a**, Reaction time on day 1 and day 15. The reaction time measured the time period from odour port exit ('unpoke') to water well entry ('choice'). The data presented here only included correct rewarded trials and incorrect non-rewarded trials. Reaction times on trial types in sequence S1 are plotted upwards, and those on trial types in sequence S2 are plotted downwards. Darker colours highlight four trial types that require rats to remember and use past sequences to perform correctly. *n* = 37 and 36 sessions on day 1 and day 15, respectively. Data are presented as mean ± s.e.m. **b**, The changes of reaction time on correct rewarded trials and incorrect non-rewarded trials during learning. **c**, **d**, The changes of reaction time during learning on the two pairs of trial types (**c**: S2a4+ and S2b5+; **d**: S2b4- and S2a5-). **e**, %Correct on all non-rewarded trial types and two (S2b4- and S2a5-) that required the recall of odour sequences. **f**, Reaction time on all non-rewarded trial types and two (S2b4- and S2a5-) that required the recall of odour sequences. Only incorrect trials (rats making a 'Go' choice on non-rewarded trials) were included. **b**–**f**, *n* = 37, 40, 40, 38, 38, 39, 38, 39, 39, 38, 39, 40, 36, 38, 36 sessions from day 1 to day 15. Data are presented as mean ± s.e.m. **a**–**d**, Two-way ANOVAs (Trial Type × Day). **e**, **f**, Two-way ANOVAs (Problem × Day). See Supplementary Table 9 for detailed statistics.
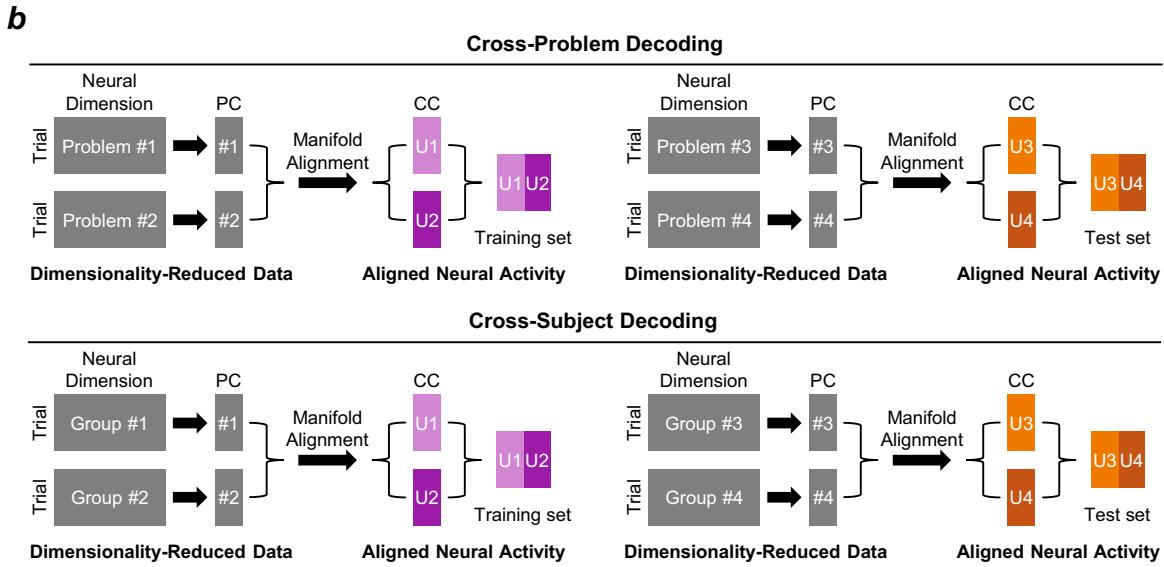

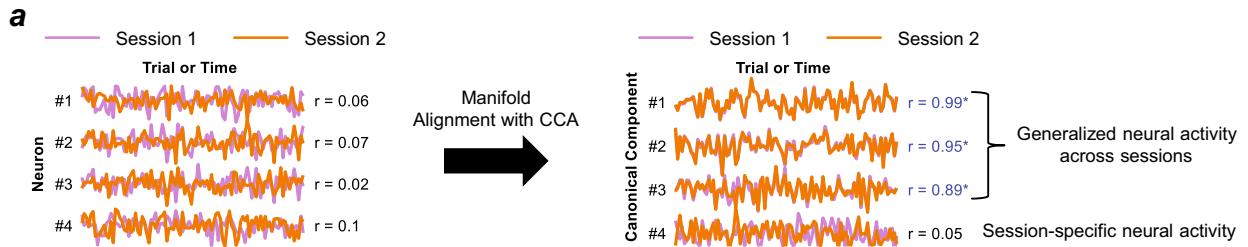

Extended Data Fig. 3 | Histology and single-unit analyses. a, Red squares show the reconstructed recording sites ($n = 18$ recording sites from 9 rats). Two electrode bundles were implanted bilaterally in OFC of each rat. Each electrode bundle consisted of 16 single wires. **b**, The number of neurons recorded across days. **c**, Cumulative distribution of neurons that showed different firing rates to all the odour stimuli. **d**, The averaged firing rates of all the neurons to all the odour stimuli. One-way ANOVA with the factor of Day: $F(14,16828) = 0.39$, $P = 0.98$. See **b** and Supplementary Tables 1 and 2 for n = number of neurons on each day. Data are presented as mean ± s.e.m. **e**, The percent of neurons that were significantly selective to at least one of the 24 trial types (one-way ANOVA; p values were adjusted by the Benjamini-Hochberg procedure to control the false discovery rate; BH-FDR; $P < 0.05$ was used to determine if one neuron was significantly selective to 24 trial types). **f**, The percent of neurons that showed selectivity to reward vs. non-reward trials (one-way ANOVA; BH-FDR; $P < 0.05$ was used to determine if one neuron was significantly selective to the current value).
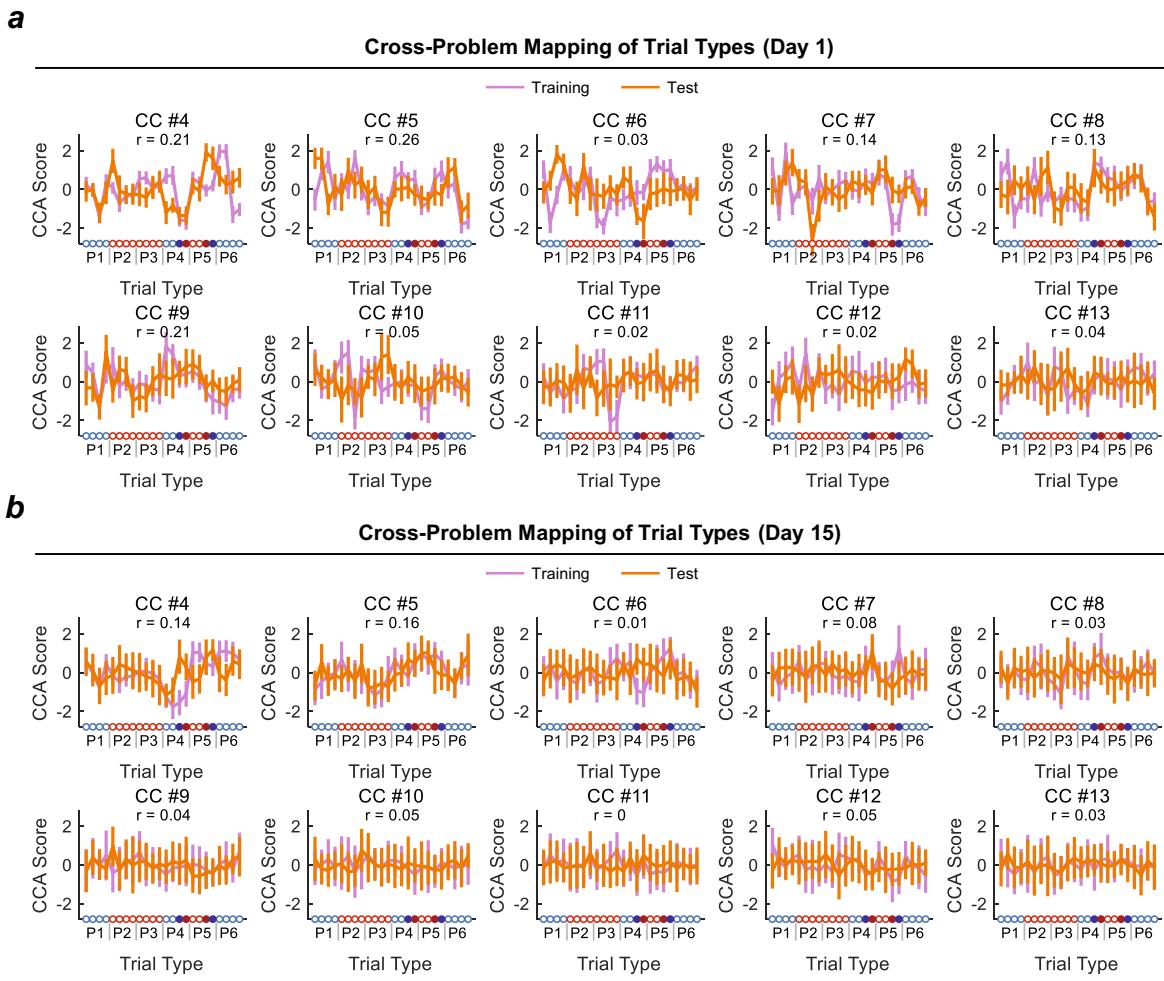

Extended Data Fig. 4 | Changes of activity space during learning. a, Using the classical multidimensional scaling (cMDS) to visualize the dissimilarity matrix shown in Fig. 2. The coloured numbers (1–6) indicate positions (P1–P6). Light blue and light red: rewarded and non-rewarded positions in S1, respectively; dark blue and dark red: rewarded and non-rewarded positions in S2, respectively. **b**, Hierarchical clustering of 24 trial types based on population neural activities on day 1. The dissimilarity matrix in Fig. 2 was used to construct a hierarchical clustering tree by an unweighted average linkage method. The clustering results were shown in dendrograms. **c**, The MDS plots to visualize the dissimilarity matrix on day 15 with the same colour code as in **a**. **d**. The hierarchical clustering analysis on day 15. **e**, Averaged pair-wise distances between 24 trial types. One-way ANOVA (factor: Day):

$F_{(14,7485)} = 2279.2$, $P = 0$, $n = 500$ repeats. **f**, Averaged pair-wise distances within reward trial types. One-way ANOVA (factor: Day): $F_{(14,7485)} = 4.4 \times 10^{-4}$, $P = 0$, $n = 500$ repeats. **g**, Averaged pair-wise distances within non-reward trial types. One-way ANOVA (factor: Day): $F_{(14,7485)} = 1.9 \times 10^{-4}$, $P = 0$, $n = 500$ repeats. **h**, The ratio of averaged pair-wise distance between and within reward vs. non-reward trials. One-way ANOVA (factor: Day): $F_{(14,7485)} = 1.1 \times 10^{-4}$, $P = 0$, $n = 500$ repeats. **e**–**h**, Data are presented as mean ± s.d. **i**, Percent of explained variance across linear discriminant components (LCs). **j**, Heatmap plots of variance distributions across LCs and training days. Warmer colour mean higher percent of variance explained by certain LC, and vice versa. Four panels were used with different coloured bar scales (from left to right: 0–1; 0–5; 0–10; 0–20) to better visualize the same result.

Extended Data Fig. 5 | Obtaining training and test sets. a, Simulation of manifold alignment with the canonical correlation analysis (CCA). Two sets of Gaussian signals ($n = 4$ for each set) were generated to represent two sets of neurons recorded from two respective task sessions. Correlations of paired neurons between sessions were controlled ($r = 0.99, 0.9, 0.85, 0.01$; Pearson correlation). The neurons between sessions were misaligned such that the correlations between paired neurons were low (shown in the left; $P = 0.58, 0.52, 0.86, 0.35$; Pearson correlation) to mimic the misalignment of neurons during experimental recording sessions. After the manifold alignment, the recovered neural components (that is, canonical components) were aligned ($P = 1.8 \times 10^{-94}, 7.0 \times 10^{-34}, 3.5 \times 10^{-27}, 0.82$; *$P < 0.05$ shown in blue; Pearson correlation). The aligned components (#1, #2, and #3) represent the generalized neural activity across sessions, while the non-correlated
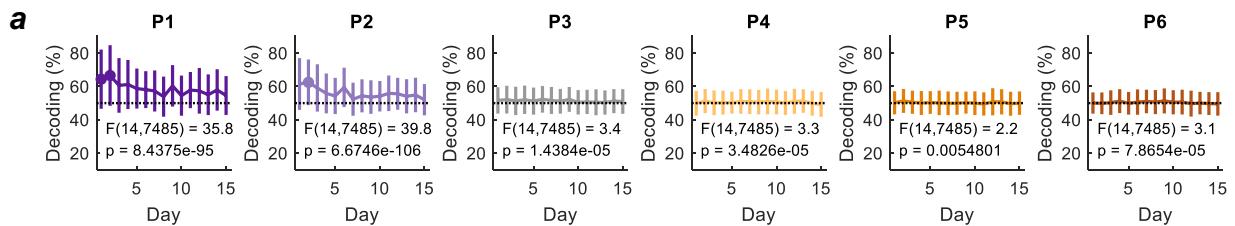

components (#4) represent session-specific neural activity. **b**, For cross-problem decoding, neurons recorded from different pairs of odour problems were separately subjected to dimensionality reduction. The resulted two matrices (480 trials × 30 principal components; PCs) were aligned through CCA to obtain two correlated matrices (U1 and U2 for training; U3 and U4 for testing; 480 trials × 30 CCs for each matrix), which were concatenated (480 trials × 60 CCs) for further use as either a training (U1U2) or test (U3U4) set. Since there were 5 odour problems in total, for each repeat, the left one was combined with one of the two problems for the training set. For cross-subject decoding, the 9 rats were randomly separated into 4 groups. Groups 1 and 2 were used to obtain the training set (U1U2), while Groups 3 and 4 were used to obtain the test set (U3U4).

Cross-Problem Mapping of Trial Types (Day 1)

b

Cross-Problem Mapping of Trial Types (Day 15)
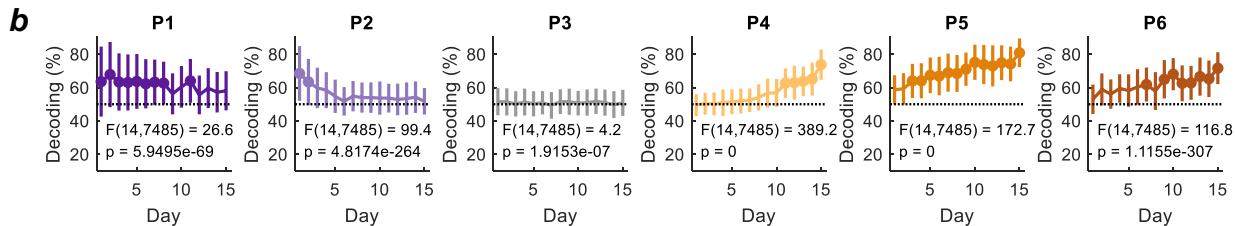

Extended Data Fig. 6 | Paired canonical components between problems. **a**, **b**, This figure is an extension of Fig. 3a. Each panel plots one pair of canonical components (CCs), one from the training set and another from the test set, starting with CC4, the first CC not plotted in the main text figure. To obtain the training set, CCA was performed on a pair of problems (for example, problem 1 and problem 2) to identify commonalities in the aligned neural subspaces. Similarly, to obtain the test set, the CCA was performed on a different pair of problems (for example, problem 3 and problem 4). The scores of paired CCs (one from the training set and the other from the test set) were plotted against the 24 trial types for both day 1 (**a**) and day 15 (**b**). The 24 trial types are ordered as P1(S1a,S1b,S2a,S2b), P2(S1a,S1b,S2a,S2b), P3(S1a,S1b,S2a,S2b), P4(S1a,S1b,S2a,S2b), P5(S1a,S1b,S2a,S2b), P6(S1a,S1b,S2a,S2b). Blue circles indicate positive trial types, and red circles indicate negative trial types. Four trial types are highlighted with filled circles (S2a4, S2b4, S2a5, and S2b5, in this order). The r in each panel is the correlation coefficient between paired CCs from the training and test sets ($n = 480$ trials for each CC; Pearson correlation). Data are presented as mean ± s.d.

**Extended Data Fig. 7 | Cross-problem decoding of sequences and positions.**
a, **b**, Cross-problem decoding of sequences S1a vs. S1b (**a**) and S2a vs. S2b (**b**) at six positions (P1 – P6). Training and test sets were generated with the same approach described in Extended Data Fig. 5b with all 480 trials. For decoding analysis in each panel, only particular trial types (for example, S1a1 vs. S1b1) were selected. A one-way ANOVA (factor: Day) was performed and shown in each panel. **c**, Confusion matrices of 6 positions (P1 – P6) as a result of the cross-problem decoding of these positions. Trial types within the same position (for example, S1a, S1b, S2a, and S2b) were lumped together. **d**, Cross-problem decoding of positions during learning. A one-way ANOVA was used to test the effect of learning: F(14,7485) = 85.4, $P = 3 \times 10^{-228}$. **e**, Confusion

matrices of the first three positions (P1 – P3) as a result of the cross-problem decoding of these three positions. Note that at each one of these three positions, the current and surrounding reward availabilities across sequences are similar, while at following positions (P4 and P5), the reward availabilities in S2b are not consistent with those in other sequences (S1a, S1b, S2a). **f**, Cross-problem decoding of the first three positions during learning. A one-way ANOVA was used to test the effect of learning: F(14,7485) = 247.8, $P = 0$. **a**, **b**, **d**, **f**, The round markers indicate that the mean decoding accuracy exceeded the 95% confidence interval (CI) of decoding accuracy from the same decoding process but with shuffled trial-type labels. Dotted line: chance level. $n = 500$ repeats. Data are presented as mean ± s.d.

a

Cross-Subject Mapping of Trial Types (Day 1)

b

Cross-Subject Mapping of Trial Types (Day 15)
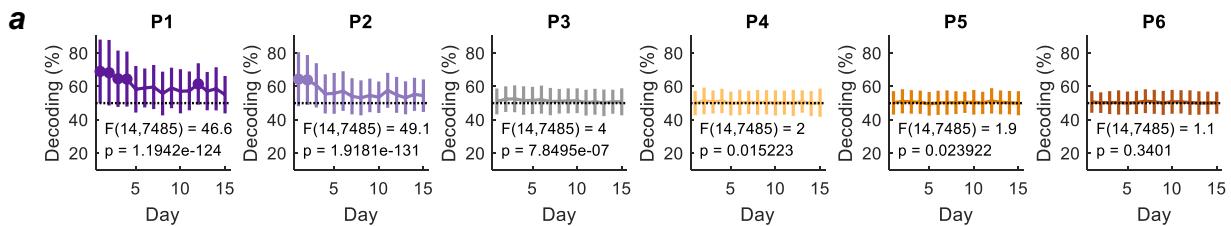

Extended Data Fig. 8 | Paired canonical components between subjects.
a, **b**, This figure is an extension of Fig. 4a. Each panel plots one pair of CCs, one from the training set and another from the test set, starting with CC 4, the first CC not plotted in the main text figure. For the training set, the CCA was performed on two groups of rats (for example, rat group 1 and rat group 2) to identify commonalities in the aligned neural subspaces. For the test set, the CCA was performed on a different two groups of rats (for example, rat group 3 and rat group 4). The scores of paired CCs (one from the training set and another from the test set) were plotted against the 24 trial types for both day 1 (**a**) and day 15 (**b**). The 24 trial types are ordered as P1(S1a,S1b,S2a,S2b), P2(S1a,S1b,S2a,S2b), P3(S1a,S1b,S2a,S2b), P4(S1a,S1b,S2a,S2b), P5(S1a,S1b, S2a,S2b), P6(S1a,S1b,S2a,S2b). Blue circles indicate positive trial types, and red circles indicate negative trial types. Four trial types were highlighted with filled circles (S2a4, S2b4, S2a5, and S2b5, in this order). The r in each panel is the correlation coefficient between paired CCs from the training and sets ($n = 480$ trials for each CC; Pearson correlation). Data are presented as mean ± s.d.
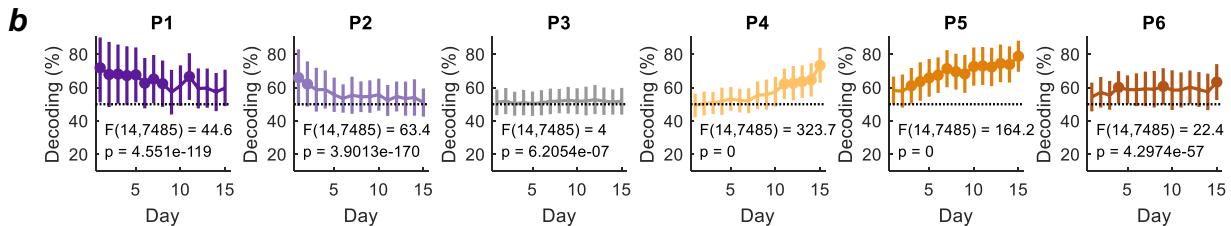

Cross-Subject Decoding of Sequences S1a vs. S1b

a

P1 — F(14,7485) = 46.6, p = 1.1942e-124
P2 — F(14,7485) = 49.1, p = 1.9181e-131
P3 — F(14,7485) = 4, p = 7.8495e-07
P4 — F(14,7485) = 2, p = 0.015223
P5 — F(14,7485) = 1.9, p = 0.023922
P6 — F(14,7485) = 1.1, p = 0.3401
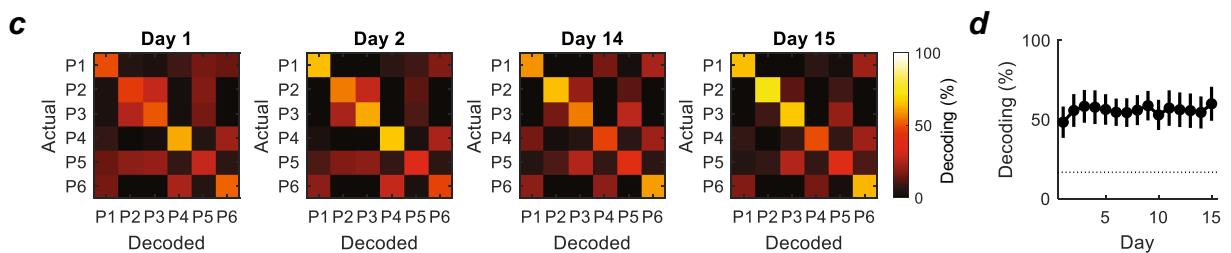

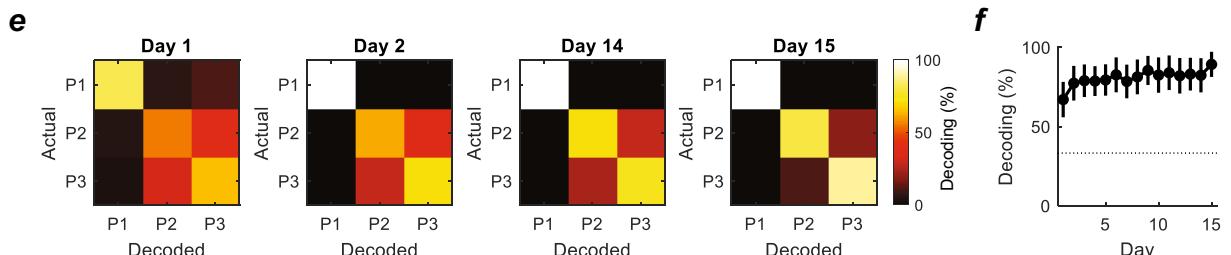

Cross-Subject Decoding of Sequences S2a vs. S2b

b

P1 — F(14,7485) = 44.6, p = 4.551e-119
P2 — F(14,7485) = 63.4, p = 3.9013e-170
P3 — F(14,7485) = 4, p = 6.2054e-07
P4 — F(14,7485) = 323.7, p = 0
P5 — F(14,7485) = 164.2, p = 0
P6 — F(14,7485) = 22.4, p = 4.2974e-57

Cross-Subject Decoding of 6 Positions (P1, P2, P3, P4, P5, and P6)

c Day 1, Day 2, Day 14, Day 15

d

Cross-Subject Decoding of the First 3 Positions (P1, P2, and P3)

e Day 1, Day 2, Day 14, Day 15

f
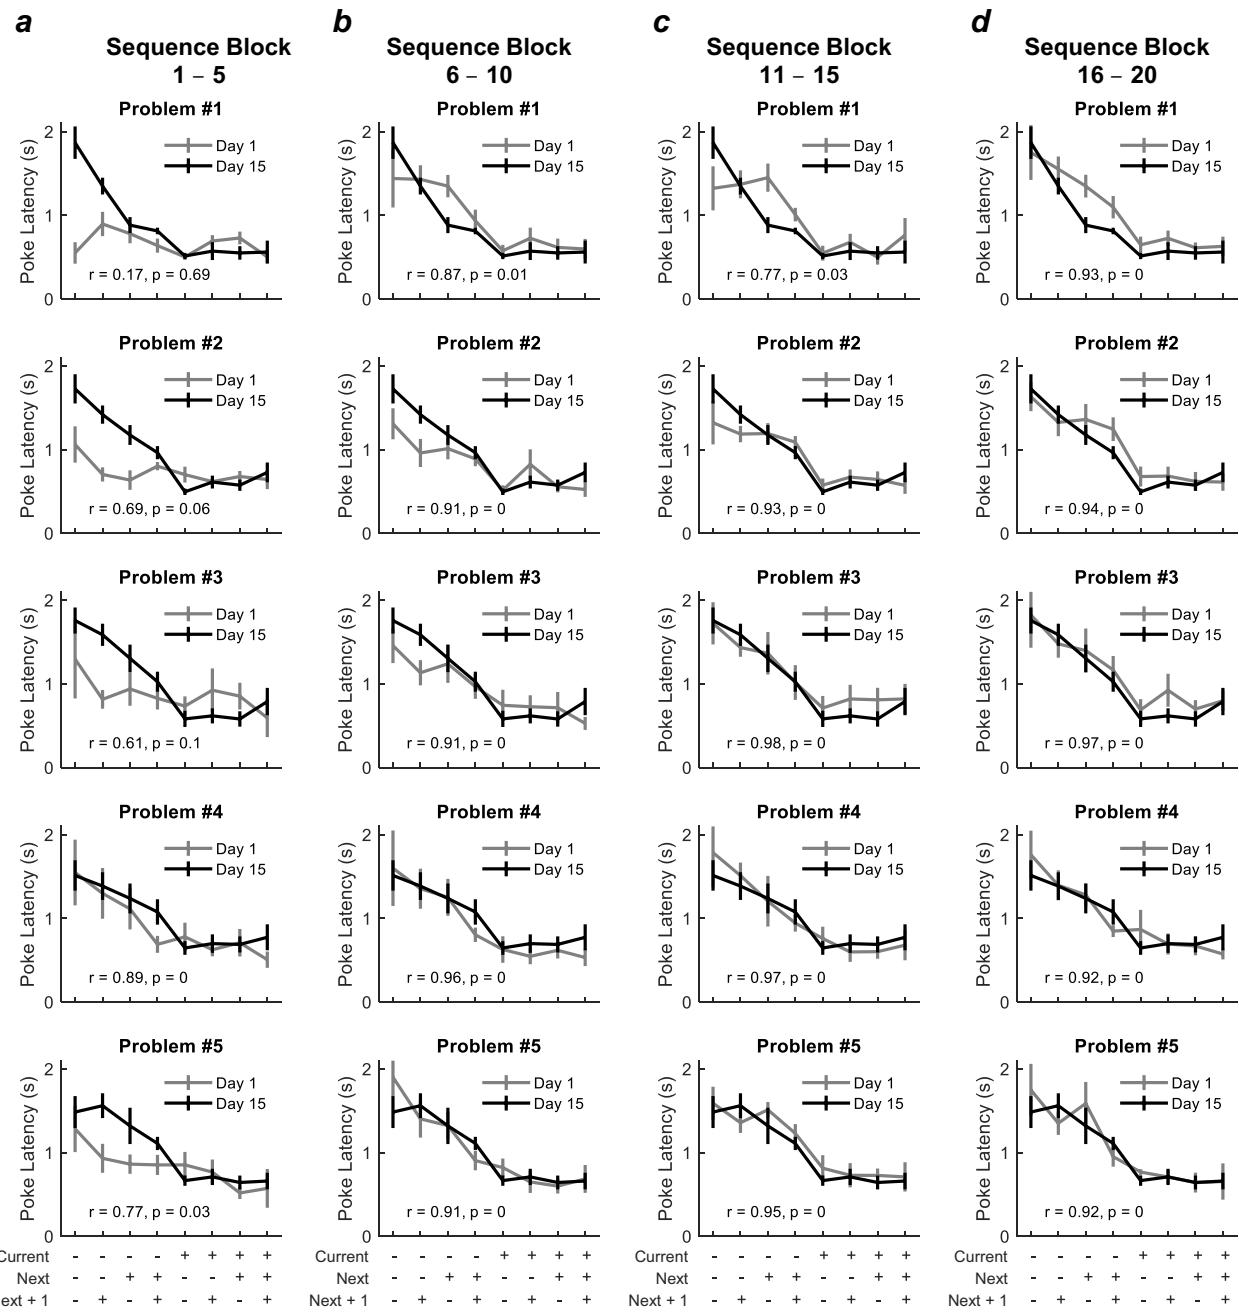

Extended Data Fig. 9 | Cross-subject decoding of sequences and positions.
a, **b**, Cross-subject decoding of sequences S1a vs. S1b (**a**) and S2a vs. S2b (**b**) at six positions (P1 – P6). Training and test sets were generated with the same approach described in Extended Data Fig. 5b with all 480 trials. For decoding analysis in each panel, only particular trial types (for example, S1a1 vs. S1b1) were selected. A one-way ANOVA (factor: Day) was performed and shown in each panel. **c**, Confusion matrices of 6 positions (P1 – P6) as a result of the cross-subject decoding of these positions. Trial types within the same position (for example, S1a, S1b, S2a, and S2b) were lumped together. **d**, Cross-subject decoding of positions during learning. A one-way ANOVA was used to test the effect of learning: F(14,7485) = 38.1, $P = 3.7 \times 10^{-101}$. **e**, Confusion matrices of the first three positions (P1 – P3) as a result of the cross-subject decoding of these three positions. Note that at each one of these three positions, the current and surrounding reward availabilities across sequences are similar, while at following positions (P4 and P5), the reward availabilities in S2b are not consistent with those in other sequences (S1a, S1b, S2a). **f**, Cross-subject decoding of the first three positions during learning. A one-way ANOVA was used to test the effect of learning: F(14,7485) = 110.16, $P = 3.1 \times 10^{-291}$. **a**, **b**, **d**, **f**, The round markers indicate that the mean decoding accuracy exceeded the 95% confidence interval (CI) of decoding accuracy from the same decoding process but with shuffled trial-type labels. Dotted line: chance level. $n = 500$ repeats. Data are presented as mean ± s.d.

Article

Extended Data Fig. 10 | Comparisons of poke latencies sorted by discounted future reward between day 1 and day 15. a–d, Poke latency measuring the time from the onset of the houselights ('light') to nosepoke ('poke') at the odour port, sorted according to discounted future reward across **a:** sequence blocks 1–5; **b**, sequence blocks 6–10; **c**, sequence blocks 11–15; **d**, sequence blocks 16–20 on day 1 (grey lines) compared to the poke latencies averaged across all 20 sequence blocks on day 15 (black lines). Each sequence block has 24 trials and comes from 24 trial types. Analyses were performed on each odour problem separately (problem 1–5; from upper to lower panels). In each panel, r is the correlation coefficient between the grey and black lines and p is the p-value for the correction. Number of sessions (that is, rats) used in the analyses: problem 1 ($n = 9$ on day 1; $n = 6$ on day 15); problem 2 ($n = 9$ on day 1; $n = 8$ on day 15); problem 3 ($n = 7$ on day 1; $n = 8$ on day 15); problem 4 ($n = 6$ on day 1; $n = 7$ on day 15); problem 5 ($n = 6$ on day 1; $n = 7$ on day 15). Data are presented as mean ± s.e.m.

Reporting Summary

Nature Research wishes to improve the reproducibility of the work that we publish. This form provides structure for consistency and transparency in reporting. For further information on Nature Research policies, see Authors & Referees and the Editorial Policy Checklist.

Statistics

For all statistical analyses, confirm that the following items are present in the figure legend, table legend, main text, or Methods section.

n/a	Confirmed	
☐	☒	The exact sample size (*n*) for each experimental group/condition, given as a discrete number and unit of measurement
☐	☒	A statement on whether measurements were taken from distinct samples or whether the same sample was measured repeatedly
☐	☒	The statistical test(s) used AND whether they are one- or two-sided *Only common tests should be described solely by name; describe more complex techniques in the Methods section.*
☐	☒	A description of all covariates tested
☐	☒	A description of any assumptions or corrections, such as tests of normality and adjustment for multiple comparisons
☐	☒	A full description of the statistical parameters including central tendency (e.g. means) or other basic estimates (e.g. regression coefficient) AND variation (e.g. standard deviation) or associated estimates of uncertainty (e.g. confidence intervals)
☐	☒	For null hypothesis testing, the test statistic (e.g. *F*, *t*, *r*) with confidence intervals, effect sizes, degrees of freedom and *P* value noted *Give P values as exact values whenever suitable.*
☒	☐	For Bayesian analysis, information on the choice of priors and Markov chain Monte Carlo settings
☒	☐	For hierarchical and complex designs, identification of the appropriate level for tests and full reporting of outcomes
☐	☒	Estimates of effect sizes (e.g. Cohen's *d*, Pearson's *r*), indicating how they were calculated

Our web collection on statistics for biologists contains articles on many of the points above.

Software and code

Policy information about availability of computer code

Data collection	Spikes and behavioral data were collected using the Plexon MAP system v2.7.0., spike sorting using Plexon Offline Sorter v4.0.
Data analysis	Data analysis was performed using MATLAB 2019a, GroupICATv4.0b, libsvm-3.22, and ndt.1.0.4. Custom MATLAB code has been made available at https://doi.org/10.17605/OSF.IO/5MH4Y

For manuscripts utilizing custom algorithms or software that are central to the research but not yet described in published literature, software must be made available to editors/reviewers. We strongly encourage code deposition in a community repository (e.g. GitHub). See the Nature Research guidelines for submitting code & software for further information.

Data

Policy information about availability of data

All manuscripts must include a data availability statement. This statement should provide the following information, where applicable:

- Accession codes, unique identifiers, or web links for publicly available datasets
- A list of figures that have associated raw data
- A description of any restrictions on data availability

The dataset used in this work has been made available at https://doi.org/10.17605/OSF.IO/5MH4Y

Field-specific reporting

Please select the one below that is the best fit for your research. If you are not sure, read the appropriate sections before making your selection.

☒ Life sciences   ☐ Behavioural & social sciences   ☐ Ecological, evolutionary & environmental sciences

Life sciences study design

All studies must disclose on these points even when the disclosure is negative.

Sample size	The number of rats (n = 9) and the number of neurons (n = 1122.9 ± 41 neurons each day with all rats and problems combined) were not predetermined by any statistical methods but are comparable to those reported in previous publications in our and other labs in the field. For example, in one recent study (Hirokawa et al., Nature, 2019), 485 neurons were recorded from lateral orbitofrontal cortex (OFC) in 3 rats. Relevant publications are cited in the Methods.
Data exclusions	No animals were excluded from analysis. Unfinished recording sessions (i.e., sessions with less than 480 trials) were excluded.
Replication	Recording experiments were conducted on one group of 9 rats. Each rat finished 5 new odor problems. For analyses that required combining all rats and problems, 500 pseudo-ensembles were generated from the same dataset for replications (dimensionality comparison). For cross-problem and cross-subject analyses, problems or rats were randomly drawn and assigned to different groups for cross-validation (500 repeats). All the analyses were consistent across repeats.
Randomization	There was only one experimental group. All rats went through the same training with the initial shaping and five new odor problems.
Blinding	Not relevant because no group allocation was involved in this study.

Reporting for specific materials, systems and methods

We require information from authors about some types of materials, experimental systems and methods used in many studies. Here, indicate whether each material, system or method listed is relevant to your study. If you are not sure if a list item applies to your research, read the appropriate section before selecting a response.

Materials & experimental systems

n/a	Involved in the study
☒	☐ Antibodies
☒	☐ Eukaryotic cell lines
☒	☐ Palaeontology
☐	☒ Animals and other organisms
☒	☐ Human research participants
☒	☐ Clinical data

Methods

n/a	Involved in the study
☒	☐ ChIP-seq
☒	☐ Flow cytometry
☒	☐ MRI-based neuroimaging

Animals and other organisms

Policy information about studies involving animals; ARRIVE guidelines recommended for reporting animal research

Laboratory animals	9 male Long-Evans rats (175 – 200 g, ~3-month-old, in the beginning of the study).
Wild animals	The study did not use any wild animals.
Field-collected samples	The study did not involve field-collected samples.
Ethics oversight	All behavioral testing was carried out at the NIDA-IRP. Animal care and experimental procedures complied with the U.S. National Institutes of Health (NIH) guidelines and were approved by the Animal Care and Use Committee (ACUC) at the NIDA-IRP.

Note that full information on the approval of the study protocol must also be provided in the manuscript.
